

# A 25-Bit Reference Resistive Voltage Divider

S. HOI TSAO, SENIOR MEMBER, IEEE

**Abstract**—An automated 25-bit reference resistive voltage divider is described. It features microcomputer-controlled self-calibration and autobalancing voltage ratio measurement to eight significant digits, with an uncertainty ( $2\sigma$ ) of three parts in  $10^8$  (of the 10-V input) or the equivalent of one least significant bit (LSB). To achieve this accuracy, sources of error have been critically examined, carefully controlled, and accounted for.

## I. INTRODUCTION

At the National Research Council of Canada, self-checking 13- and 22-bit voltage dividers have been built and evaluated [1], [2]. They are based on a switching technique for resistive voltage dividers by Cutkosky [3]. The uncertainty in the voltage ratios they provide is typically a few parts in  $10^7$  of the 10-V input.

In the 25-bit reference voltage divider and calibration system to be described, higher accuracy and precision have been achieved by dealing concretely with the small but finite effects of the divider's switch contact, wiring, leakage, and output resistances on the calibration and on the ratio realized. As a result, it can measure arbitrary voltage ratios (between 0 and 1) to eight significant digits with an uncertainty ( $2\sigma$ ) of three parts in  $10^8$  of the input, or the equivalent of one least significant bit (LSB). The experimental verification of its accuracy will also be described.

## II. SYSTEM DESCRIPTION

A block diagram of the automated system is given in Fig. 1. The 25-bit voltage divider is entirely passive. It consists of an improved 13-bit self-checking (Cutkosky) divider terminated by a 12-bit potentiometer. Thus the higher-order Cutkosky divider provides the composite divider with the requisite accuracy, while the potentiometer extends its resolution without increasing its output resistance [4]. As before, switching is effected by latching relays, simply controlled and monitored by a microprocessor which also interfaces to the IEEE-488 bus. The two main system operations, autocalibration and autobalancing ratio measurement, are designed to be software driven by the desktop computer. This makes an extremely versatile system which may be tailored for the experimental investigation of systematic errors as well as for other customized applications.

The 13-bit divider is made up of  $40\text{-k}\Omega$  ( $R_{\text{nom}}$ ) wire-

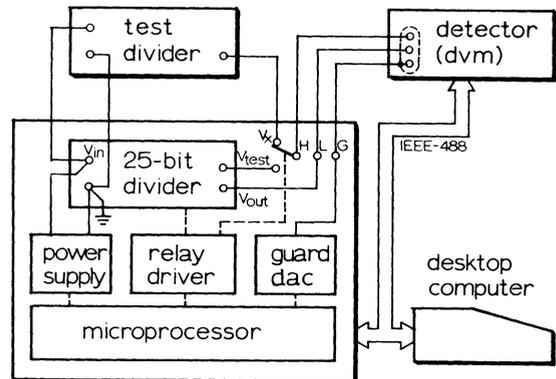

Fig. 1. Block diagram of the automated reference voltage divider system using a DVM as detector, shown calibrating a test divider.

wound resistors, initially matched to  $\pm 20 \times 10^{-6}$ ; the 12-bit potentiometer is made from 0.01-percent metal-film resistors contained in one package. In practice, however, only the first 10 or 11 binary stages of this divider were found to require periodic recalibrations or corrections. The calibration routine takes about 90 s to complete, and is less sensitive to external influences than the ratio measuring routine.

The system detector is a digital voltmeter (DVM) of 100-nV resolution. Throughout this paper, a  $\pm 10\text{-V}$  input is assumed, and each measurement calls for eight DVM readings, four taken in each reversed dc polarity. The DVM helps to speed up the autobalancing process in ratio measurements, but its nonlinearity hardly matters because the final imbalance never exceeds  $\pm 25 \mu\text{V}$ . Unless otherwise stated, all uncertainties will be  $1\sigma$  estimates.

## III. ERROR CONSIDERATIONS

The following analyses deal mainly with the errors of the Cutkosky divider on which the accuracy of the system depends.

### A. Autocalibration

Let  $G_i = V_{\text{out}}/V_{\text{in}}$  be the voltage transfer ratio of the  $N$ -bit divider ( $N = 13$  in this case) and let  $T_j = 0$  or  $1$  ( $j = 1, 2, \dots, N + 1$ ) denote the individual setting of the toggle switches of the divider (Fig. 2).

Cutkosky [3] has shown that it is sufficient to make  $2N$  individual measurements to completely calibrate an  $N$ -bit divider, neglecting switch and wiring resistances. Referring to the divider of Fig. 2, the self-checking or autocalibration process consists of following an established switching sequence and making  $N$  pairs of measurements

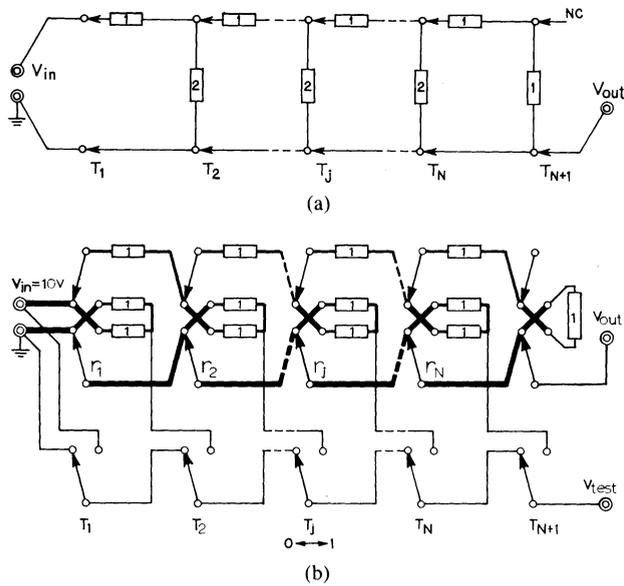

Fig. 2. (a) An  $N$ -bit Cutkosky voltage divider with cascaded DPDT switches  $T_j$ , each drawn as a pair of interchangeable contacts. With all switches at zero (as shown), all horizontal "dropping resistors" appear in the upper branch. Resistance values indicated are relative to  $R_{nom}$ . (b) Wiring diagram for the same divider. Heavy links identify the requisite low-resistance connections. Additional SPDT switches give access to internally generated  $V_{test}$  for self-checking purposes.

of the normalized quantity  $d = (V_{out} - V_{test})/V_{in}$ . For example, to calibrate the  $k$ th stage, one measures  $d_{k,1}$  with  $T_{k+1}$  set to 1 and all other switches to 0, and then  $d_{k,2}$  with  $T_k$  also set to 1. Hence, a set of  $N$  differences,  $\Delta_j = d_{j,1} - d_{j,2}$ , can be calculated, each  $\Delta_j$  being a measure of the "resistance mismatch" in the  $j$ th stage.

From the above set of  $\Delta_j$ 's the ratio  $G_t$  may be computed in a number of ways [1], [3] for any given switch setting configuration of the divider. The following alternative approach is found to be useful in dealing with the introduction of switch and wiring resistances. Since derivations of the equations to follow are often lengthy but straightforward, only the reasoning behind them will be given.

To begin with, let the voltage developed across the "dropping resistor" in the  $j$ th stage, when divided by  $V_{in}$ , be the "weight"  $w_j$  of that stage, which carries a nominal value of  $1/2^j$ . To account for the small resistance mismatches ( $\Delta_j \ll 1$ ) in a cascade of stages, these  $N$  weights can be computed as follows:

$$w_1 = (1 - \Delta_1)/2$$

$$w_2 = (w_1 + \Delta_1 - \Delta_2)/2 = (1 + \Delta_1 - 2\Delta_2)/2^2$$

and in general

$$w_j = (w_{j-1} + \Delta_{j-1} - \Delta_j)/2. \quad (1)$$

Hence,  $G_t$  can be obtained as a summation of the form

$$G_t = \sum_{j=1}^N (b_j w_j) \quad (2a)$$

$$\approx \sum_{j=1}^N (b_j/2^j) \quad (2b)$$

where the binary coefficient  $b_j$  depends on whether the  $j$ th bit is ON ( $b_j = 1$ ) or OFF ( $b_j = 0$ ). In the circuit representation of Fig. 2(a), it is apparent that switching any dropping resistor into the lower branch of the circuit directly between  $V_{out}$  and ground effectively turns that bit ON, because its voltage drop contributes directly to  $V_{out}$ . By inspection, the "down/up" location of each dropping resistor in terms of  $b_j$  can be derived from the following logical equation:

$$b_j = T_j \oplus b_{j-1}, \quad b_0 \equiv 0. \quad (3)$$

Conversely, in trying to realize a transfer ratio of  $G_t$ , the approximation (2b) can be solved for  $b_j$ 's and the required switch settings can be derived from the dual relationship of (3), viz.

$$T_j = b_j \oplus b_{j-1}, \quad b_{N+1} \equiv 0. \quad (4)$$

The assessment of the uncertainty in  $\Delta_j$  forms an important part of this study. Each  $\Delta_j$  is obtained from the difference of two successive measurements; it is influenced by the switches' thermal EMF and the detector input noise and drift. Any common-mode dependence of  $\Delta_j$  would constitute a systematic error and should be eradicated. Numerous sets of autocalibrations were conducted to examine the effects of the common-mode and guard voltages, delay, and integration times for taking a DVM reading, etc. It was found that using a driven guard circuit (Fig. 1) and reversed dc measurements delivers the smallest uncertainty in autocalibration. The pace of the calibration operation has also been optimized by starting with the LSB and by tailoring the necessary time delays. Through numerous repeated autocalibrations with the chosen DVM, it has become quite clear that each measurement of any one  $\Delta_j$  by the adopted routine is uncertain by  $\pm 7 \times 10^{-9}$ . How much this would contribute to the uncertainty in the resulting  $G_t$  could be calculated in each case from (1) and (2), but this is rarely done in practice. Instead, a worst-case uncertainty of  $\pm 9 \times 10^{-9}$  may be assigned, which is equal to  $\sqrt{N+1}/3$  times the above value (cf. [3, section III]).

### B. Switch and Wiring Resistances

The switches used in the driver must meet certain thermal EMF, insulation-, and contact-resistance requirements. Based on experience, pulse-operated latching relays are used. The armatures of these relays work with gold-plated contact pads that have been carefully laid out and interconnected (and reinforced with copper strips where necessary) on a printed circuit board. Contact-resistance measurements on isolated relays of this type gave  $32 \pm 1.2$  m $\Omega$  as typical for one set of contacts, and  $(32/n) \pm (1.2/\sqrt{n})$  m $\Omega$  for  $n$  paralleled contacts. To control uncertainty, multiple relay contacts are employed for the first five switches. Noting that the current is halved in each succeeding switch, one can estimate ratio corrections for the divider as in Table I. Wiring resistances (assumed fixed) will increase these estimates but the uncertainties should remain. This has been confirmed by

TABLE I  
VOLTAGE RATIO CORRECTIONS ( $1\sigma$  ESTIMATES) FOR DPDT SWITCHES IN  
THE 13-BIT DIVIDER

SWITCH #	PARALLELED CONTACTS/POLE	CONTACT RESISTANCE (m $\Omega$ )	V RATIO CORRECTION (10 <sup>-6</sup> )

measurements. The results of these effects in determining  $G_i$  will be examined next.

Using Fig. 2(b) as a model, one notes that switch and wiring resistances in series with the dropping resistor may be considered an integral part of the latter. On the other hand, those resistances in series with the "zero-resistance" connecting links should be accounted for. For the sake of brevity in the following analysis, they are expressed as resistive ratios  $r_j$  with respect to the  $R_{nom}$  of the divider. If  $e_j$  denotes the voltage across  $r_j$ , it follows that  $e_j = V_{in} \cdot r_j/2^j$  and that the following summation

$$q = \sum_{j=1}^N (r_j/2^j) = \sum_{j=1}^N (e_j/V_{in}) \quad (5)$$

is simply the ratio of the sum of voltage drops across all  $r_j$ 's to  $V_{in}$ .

Suppose that a set of  $\Delta_j$ 's is experimentally determined as before and that a set of  $w_j$ 's is computed as in (1). The problem is how to formulate  $G_i$  to account for the presence of  $r_j$ 's.

In contrast with the ideal-contact case, further analysis shows that each  $\Delta_j$  now contains a contribution from twice the voltage drops across succeeding (lower-order) switches, and that the actual weight  $w_j'$  has a residual value of  $r_j/2^j$ , even when that bit is OFF ( $b_j = 0$ ). The situation can best be summarized by the following two equations:

$$\begin{aligned} w_1' &= [r_1 + b_1(1 - \Delta_1)(1 - 2q)]/2 \\ w_2' &= [r_2 + b_2(1 + \Delta_1 - 2\Delta_2)(1 - 2q)]/2^2 \\ &\vdots \\ w_j' &= [r_j + b_j(1 + \Delta_1 + \cdots + \Delta_{j-1} - 2\Delta_j) \\ &\quad \cdot (1 - 2q)]/2^j \end{aligned} \quad (6)$$

and

$$G_i' = \sum_{j=1}^N w_j'. \quad (7)$$

Since the individual  $r_j$  in the actual circuit is difficult to ascertain, the individual  $w_j'$  cannot be determined and it appears that  $G_i'$  cannot be calculated precisely from (7). However, (7) can be rewritten as

$$G_i' = q + (1 - 2q) \sum_{j=1}^N (b_j w_j) = q + (1 - 2q)G_i \quad (8)$$

which is a very useful result indeed. First, one determines  $G_i$  exactly as before, in spite of contact and wiring resistances. Second,  $q$  may be obtained from one single *in-situ* measurement of  $V_{out}/V_{in}$  with all switches set to 0. Third,  $G_i'$  is calculated from  $G_i$  in a manner analogous to a "renormalization" of the ratio with respect to remote input terminals. Therefore, the effect of (small) wiring resistances from the divider to the remote input terminals is transparent to the user if the input wiring detail shown in Fig. 2(b) is followed.

### C. Loading

The output resistance  $R_{out}$  of the Cutkosky divider can be calculated precisely [4]. For the 13-bit divider at hand, it has a maximum value of  $3.1 \times R_{nom}$  or nearly 0.125 M $\Omega$ , and it is most frequently distributed around the value of  $2.5 \times R_{nom}$  or 0.1 M $\Omega$ . These being fairly large resistances, both internal leakage and external loading must be carefully controlled so that one can interrelate the voltage and resistance ratios of this divider with confidence.

Internal leakage or loading is minimized by adopting a sensible relay-board layout. The latching relays are driven through opto-triacs by a transformer-coupled 60-Hz supply, whose common is connected to the guard voltage. This is particularly effective in controlling the leakage from the lower order stages of the divider (where  $R_{out}$  is higher).

Inasmuch as this is a ground-referenced system, loading between  $V_{out}$  and ground must be controlled and accounted for. The addition of an isolation amplifier to this divider's output has not been pursued for fear of compromising its overall performance. A small number of commercial DVM's compatible with the use of a driven guard circuit were examined as a differential detector for the system. In general, the input HI-to-ground resistance (RHG) is much larger than the input LO-to-ground resistance (RLG). Therefore, it is prudent to present the input HI to the unknown voltage  $V_x$  (e.g., from the test divider in Fig. 1) whose precise source resistance is not always known. The chosen DVM has an RHG in excess of 8 T $\Omega$ . Its RLG amounts to  $< 0.02$  T $\Omega$  without a driven guard and increases to 0.20 T $\Omega$  when guarded at the mean input potential. Measurements showed that its RLG is moderately time-dependent after a dc reversal and that it could vary up to  $\pm 15$  percent. The resulting maximum correction of  $(-0.62 \pm 0.09) \times 10^{-6}$  would not be acceptable. To

TABLE II  
UNCERTAINTY ASSIGNMENT FOR THE DIVIDER

Source	$1\sigma$ Estimate
Autocalibration Correction	$\pm .009 \times 10^{-6}$
Switch,wiring Correction	$\pm .008$
Detector Loading Correction	$\pm .009$
Potentiometer	$\pm .005$
Allowable Drift after Cal.	$\pm .005$
Simple Sum	$\pm .036 \times 10^{-6}$
Root-sum-squares	$\pm .017 \times 10^{-6}$

overcome this problem, the effective RLG must be increased.

To this end, the guard circuit was overdriven and the system was programmed to measure the correction, when  $R_{out}$  was loaded by RLG, as a function of both the guard overdrive and the elapsed time after a dc reversal. As a result of this study, a guard voltage equal to 112 percent of the mean input potential is adopted in order to limit the measurable maximum correction to  $(-0.071 \pm 0.009) \times 10^{-6}$  (i.e., RLG = 1.7 T $\Omega$ ) when readings are taken 6–8 s after a dc reversal. Measuring this correction can be included as a part of the calibration routine.

#### D. Overall Uncertainty

Table II sums up the various uncertainties from identified sources. The switch and wiring correction uncertainty has been adjusted by  $\sqrt{2}$  to reflect the situation of two poles/switch. Since the sources are not correlated, summing these uncertainties by root sum squares (RSS) is justifiable. A  $2\sigma$  estimate for the total RSS uncertainty amounts to  $\pm 0.034 \times 10^{-6}$  or the equivalent of 1 LSB of this 25-bit divider.

#### IV. VERIFICATION

The elegantly simple method of obtaining self-checking resistive ratios by Thompson [5] was adopted for the purpose of verifying the divider accuracy. With only six nominally equal resistors, very accurate voltage ratios of  $n/10$  ( $n = 1, 2, \dots, 9$ ) are provided by the geometric mean of the ratios realized from the dual-network configurations (Fig. 3).

The resistive ratio device constructed for the above purpose uses a stud-and-plug interconnection arrangement (Fig. 4), where heavy copper studs (hexagonal blocks) are mounted on a thick polytetrafluorethylene (PTFE) sheet. The seven numbered studs have six 40-k $\Omega$  wirewound resistors (matched to  $\pm 0.005$  percent) soldered to alternate ends of their center posts, in sequence. Thus, the node between resistors can be thought to locate itself at the geometric center of the stud. The resistance between adjacent nodes was found to be  $46 \pm 6 \mu\Omega$  when a copper plug was inserted into the rimmed hole between them. Therefore,

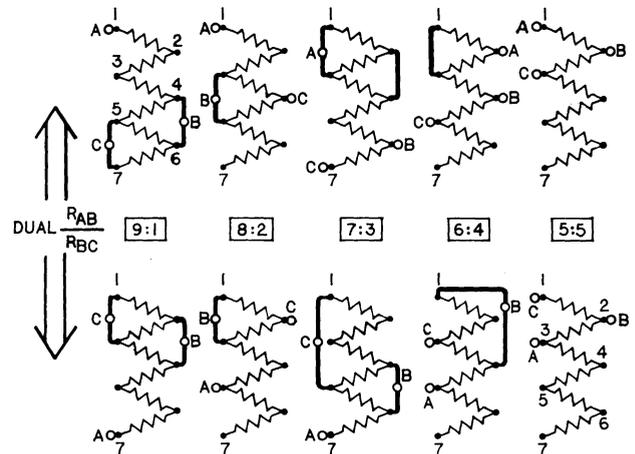

Fig. 3. Dual configurations of networks (after Thompson [5]) producing resistance ratios for each step of a single-decade divider. Network has six nominally equal resistors connected in series. Thick lines represent shorting links.

two 40-k $\Omega$  resistors could be connected in parallel with about  $1 \times 10^{-9}$  error. The lettered studs were used as terminals for accessing the resistance ratio produced.

Following Thompson's circuits (Fig. 3) the resistive ratio device was configured (by means of up to five plugs) for a ratio of  $n/10$ , immersed in a 23.00 $^{\circ}\text{C}$  oil bath and measured by the fully corrected divider (in terms of a voltage ratio). The network was inverted end for end and the resulting complementary ratio  $(1 - n/10)$  measured. Then the dual-network configuration for the same ratios was implemented and measured. Using  $n = 1, 2, \dots, 5$ , five sets of measurements were made and the results have been tabulated as items (A) and (B) in Table III. One notes that the sum of the complementary ratios from inverted networks should add up to unity, a necessary condition for good accuracy. Geometric means (C) should be perfect ratios of  $n/10$ , except for the consideration of a small load coefficient of  $-0.025 \times 10^{-6}/\text{mW}$ . Based on the changes in dissipation between configurations, small corrections (D) can be applied. Deviations of the corrected results (E) from perfect  $n/10$  would indicate the accuracy of the divider at those ratios. As can be seen, these deviations are less than the above  $2\sigma$  uncertainty estimate.

Finally, the binary divider settings that produce ratios of  $n/10$  do not have an obvious correlation with one another, and there is every reason to believe any arbitrary ratio produced should be equally valid. To attempt to verify this point, the divider was also compared with a manually adjusted Kelvin-Varley divider over many decades and on several occasions. Although first-decade ratio discrepancies were occasionally found to be as large as  $0.12 \times 10^{-6}$ , most incremental ratio comparisons showed much smaller discrepancies.

#### V. CONCLUSION

To fully exploit the self-checking feature of the Cutkosky divider, this paper addresses the problems arising

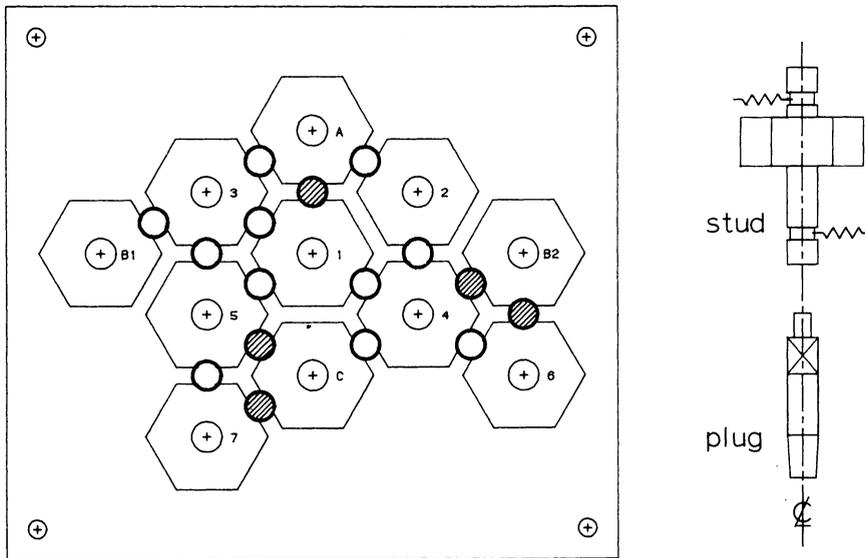

Fig. 4. Copper stud-and-plug arrangement for producing resistance ratios of  $n/10$ . Six equal resistors are connected between the seven numbered studs. Circles between studs locate rimmed holes to receive up to five shorting plugs. As an example, with plugs inserted into the shaded holes, the ratio  $R_{BC}/R_{AC} (= 1/10)$  is accessible through terminals A, B<sub>2</sub>, and C.

from switch and wiring resistances, as well as from output loading, and offers practical solutions to these problems. It has resulted in an automated 25-bit reference voltage divider system whose ratio corrections and measurement uncertainties arising from identified sources have been carefully examined.

The total uncertainty of this divider system has been given a  $2\sigma$  estimate of  $\pm 0.034 \times 10^{-6}$ . An accurate self-checking resistive ratio device has been built and used to verify the proper application of corrections to the divider and the absence of any significant systematic errors.

Through periodic autocalibrations the high accuracy of this reference divider can be reliably maintained, which is obviously an important consideration for standard laboratory applications. This divider has been used in the

calibration of 7-decade voltage dividers and solid-state voltage references.
